# STEREOTYPES AND BELIEF UPDATING*

Leena Kulkarni

August 15, 2019

**Abstract:** We explore how self-assessments respond to feedback about own ability across a range of tasks, with a particular focus on how gender stereotypes impact belief updating. Participants in our experiments take tests of their ability across different domains. Absent feedback, beliefs of own ability are strongly influenced by gender stereotypes: holding own ability fixed, individuals are more confident in gender congruent domains. We then provide noisy feedback about own absolute performance to participants and elicit posterior beliefs. Gender stereotypes have significant predictive power for posterior beliefs, both through their influence on prior beliefs (as predicted by a Bayesian model) but also through their influence on updating (a non-Bayesian channel). Both men and women's beliefs are more responsive to information in gender congruent domains than gender incongruent domains. This is primarily driven by differential reactions to exogenously-received good news about own ability: both men and women react more to good news when it arrives in a gender congruent domain than when it arrives in a gender incongruent domain. Our results have important implications for understanding how feedback shapes, and perpetuates, gender gaps in self-assessments.

**Introduction**

Beliefs about own ability are key inputs into many economically significant decisions. They shape financial decision-making and educational choices, such as what schools to apply to and what fields to study. They also likely impact labor market outcomes, shaping how job candidates present themselves and what opportunities they apply to. Across each of these contexts, there exist varying degrees of uncertainty and ambiguity, creating the space for biases to flourish. In fact, across each of these contexts, important gender differences in beliefs have been documented (Barber and Odean 2001 on finance; Pan 2018 and Buser et al 2014 on education; Reuben et al 2014 and Exley and Kessler 2019 on self-presentation; and Coffman et al 2019 on job applications).

One important source of bias is self-stereotyping. Across many studies, researchers have documented a gender gap in beliefs about own ability, primarily in male-typed fields, where perceived and/or actual gender gaps in performance favor men. That is, conditional on having the same measured ability, women have been found to have more pessimistic beliefs about own ability compared to men in male-typed fields. For instance, given the same ability in a number-adding task, women believe they rank worse relative to others than men do (Niederle and Vesterlund 2007). This gender gap has been found in studies that focus on "estimation", where participants estimate their own absolute performance on a task (Lundeberg, Fox, and Punćcohaŕ 1994, Deaux and Farris 1977, Pulford and Colman 1997, Beyer 1990, Beyer and Bowden 1997, Beyer 1998, Coffman 2014, Bordalo et al 2018), and in studies that ask about believed ability relative to others (like Niederle and Vesterlund 2007, and also Grosse and Reiner 2010, Dreber, Essen, and Ranehill 2011, Shurchkov 2012).

Given the existence of these gender gaps and the importance of beliefs in driving decision-making, a natural question is why these gaps persist, and what might we do about them.[1] Perhaps the most obvious solution is providing increased information. If a student is unsure of her abilities in STEM, her school could provide her with more feedback about her talents in this area (based on test scores, or teacher recommendations). Or, if an entry-level employee is unsure whether she possesses the qualifications needed to apply for an internal promotion, her manager could provide a more detailed performance review that addressed these areas. If uncertainty is a driver of biases in beliefs of own ability, increased (objective) information about own ability would seem to offer a promising path toward reducing gender gaps in beliefs.

---

[1] Of course, another natural question is, taken these gender gaps as a given, how can we modify our processes and institutions in such a way that biased beliefs are less distortionary for outcomes? While not the focus of this paper, this is another important issue to wrestle with and is addressed in concurrent work by the authors (Coffman et al. 2019).

Our goal in this paper is to provide an empirical investigation of the effectiveness of increased information in reducing gender gaps in beliefs of own ability. We ask whether and how biased beliefs persist in the face of highly accurate, task-specific feedback. In particular, we run a series of experiments that explore how individuals update their beliefs about themselves in response to noisy but quite informative feedback about own ability. A central focus of our work is understanding the role of gender stereotypes in driving gender differences in reactions to this information. We know that stereotypes have important predictive power for individuals' beliefs about their own ability - absent feedback (Coffman 2014, Bordalo et al 2018). Is it also the case that these gender stereotypes have predictive power for how individuals incorporate new information into their beliefs?

In our first experiment, participants complete a timed test of cognitive ability. After completing the test, we elicit an incentivized belief of their absolute score on the test from all participants. Then, we provide noisy information. Across two randomly-assigned conditions, we vary the precision of the signal received: half of our participants receive a signal that is equal to their true score with probability 0.6 and half receive a signal that is equal to their true score with probability 0.9. In both treatments, signals are equal to a participant's true score with probability $p$ (either 0.6 or 0.9 depending on treatment), and with probability $1-p$, the signal is constructed by adding an integer drawn from a uniform distribution over {-5,-4,-3,-2,-1,1,2,3,4,5} to their true score. Note that this feedback is informative, immediate, task-specific, and individualized; thus, in many ways, we have attempted to create the "best-case scenario" for the effectiveness of feedback.

After transmitting these signals, we again elicit an incentivized belief of own absolute score on the test, allowing us to explore how participants update their beliefs. Across our two signal treatments, we find that, conditional on measured ability, women's priors of their own absolute test scores are approximately 0.13 standard deviations of ability lower than men's, a statistically significant gap. Providing noisy but informative signals of own ability does not significantly reduce this gender gap. After the provision of signals, the gender gap remains at 0.12 standard deviations of ability. Interestingly, the gender gap directionally increases with feedback in the 90% Signal Accuracy treatment, suggesting that moving to more informative signals of own ability does not more effectively close the gap.

Our results motivate us to consider what underlies the ineffectiveness of information in closing the gender gap in beliefs. We design a second study to tease apart different mechanisms. In particular, we ask what the role is for gender stereotypes in predicting responses to information. We use a similar experimental paradigm, but expand the range of domains we consider. Rather than focus on cognitive ability, we test participants across eight different domains, chosen to vary in their associated gender stereotype. This allows

2

us to ask the question of whether reactions to information depend upon whether that information arrives in a gender congruent domain (i.e. more male-typed for men, or more female-typed for women).

Participants in the second study complete three rounds of an experiment very similar to Study 1. In each round, they take a test of their ability in a randomly-assigned domain. They then provide an incentivized prior belief of both their absolute performance in that test and their belief of their rank relative to others completing the same test. We use the same signal structure as Study 1, but with signal accuracy probabilities of *p=0.5* and *p=0.7*. We then collect posterior beliefs, both of absolute and relative ability. In addition, in Study 2, we explicitly collect data not only on their point-wise prior and posterior beliefs of absolute ability (what is your most likely score on the test?), but also on their full prior and posterior distributions over all possible scores. This allows us to speak to gender differences in the shape of belief distributions, and create a Bayesian benchmark for updating behavior for each participant. This framework allows us to parse the results we observe, and uncover systematic departures from the Bayesian model.

In line with past work, we find a significant role for stereotypes in predicting prior beliefs, both of absolute and relative ability. Holding fixed measured ability, individuals' beliefs of their own ability increase significantly as the category becomes more gender congruent.

After the provision of information, stereotypes continue to play a significant role in predicting beliefs. Stereotypes have an impact on posteriors, both through their impact on participant priors (as predicted by the Bayesian model) but also through their impact on how participants react to information given the same prior (a non-Bayesian channel). On average, we find no gender differences in how predictive the Bayesian model is for men and women: the overall pattern is that participants demonstrate conservatism relative to the Bayesian prediction. However, we find that the extent of conservatism depends significantly on gender stereotypes. Men are significantly more responsive to information in male-typed domains, while women are significantly more responsive in female-typed domains.

Because of our signal structure, we are able to explore how updating varies depending upon whether the signal draw was "good" or "bad" news. Importantly, in our design, the assignment of good or bad news through the randomly-drawn noise term is completely exogenous to both true ability and prior beliefs, creating a clean test of asymmetric responses. We find that reactions to good and bad news vary with the gender stereotype of the domain. In particular, participants seem to respond more to stereotype-confirming news. For instance, both men and women are more responsive to good news when it arrives in gender congruent domains than when it arrives in gender incongruent domains. And, in gender incongruent domains, both men and women are more responsive to bad news than good. Our results suggest that

convincing people of their talent in gender incongruent domains may be particularly challenging, as individuals seem to discount positive information in these areas.

Our paper follows a growing literature on understanding how individuals update beliefs in response to feedback on own ability. Most prior studies have focused on beliefs of relative ability, using coarse paradigms to allow for clean and practical tests of Bayesian models. For instance, a participant might be asked their belief about the probability of placing in the top half of performers, and then receive a noisy binary signal of whether they are indeed in the top half. With this structure, one can elicit relatively simple prior distributions over placement possibilities and compare updating behavior to a full Bayesian benchmark (see, for instance, Mobius et al 2014, Barron 2016, Buser et al 2016, Coutts 2018, Gotthard-Real 2017, Ertac 2011). Eil and Rao (2011) operate in a finer response space, eliciting full belief distributions over relative placement in a population in terms of IQ and beauty (and in a non-ego-relevant control task). One main takeaway from this literature is that participants update differently about themselves than they do when forming beliefs about arbitrary statistical processes, though the differences are not entirely consistent across study. Some studies have found evidence for a "good news – bad news effect", with participants responding more to positive signals than negative signals (Eil and Rao 2011, Mobius et al 2014), though this finding is not universal.[2] Similarly, there is evidence that people are more confident about their probability of being among the top performers when they are motivated to be so, either because of strategic considerations (Schwardmann and van der Weele 2018) or when the task is more ego-relevant (Buser, Gehards, and van der Weele 2016), consistent with theoretical models of motivated reasoning (such as Rabin and Schrag 1999, Benabou and Tirole 2002, or Koszegi 2006).

Results on gender within this literature have been mixed. Mobius et al (2014) report that women demonstrate more conservatism than men in their ego-relevant context, updating less in response to information, but that there are no gender differences in asymmetry. Coutts (2018) finds very similar results on gender, reporting no gender differences in asymmetry and evidence of more female conservatism (but in both ego-relevant – a math and verbal quiz -- and neutral settings). Ertac (2011) finds mixed results, with women responding less to "good news" than men do about a verbal task, but not about an addition task. In recent work, Shastry, Shurchkov, and Xia (2018) explore how noisy feedback on relative ability shapes tournament entry decisions. They find that negative feedback is a strong deterrent of tournament entry for high ability women, primarily because they are too likely to attribute this feedback to ability rather than luck. Because these studies vary in their paradigms and tasks used, it is hard to know what underlies the across-study differences.

---

[2] In particular, Ertac (2011) finds that participants respond more to bad news than good in her ego-relevant task.

In our study, we will attempt to unpack the role of stereotypes in driving gender differences in beliefs. Rather than simply compare men and women in a single domain, and attribute any differences to gender, we will compare men and women across a range of domains, and ask how, holding all else fixed, the gender-type of the environment matters for decision-making. To do so, we will systematically vary the gender-type of the domain, taking care to hold all other aspects of the environment as fixed as possible.

In addition, by focusing on absolute ability rather than relative ability, our experiment will yield rich data on good and bad news. Men and women across the ability spectrum will be equally likely to receive exogenous good or bad news (of equal accuracy). Because participants are updating on absolute ability, the space of possible beliefs will be quite fine, potentially allowing for identification of more subtle differences.[3] Our results suggest that past findings of greater female conservatism could possibly be explained by (i) a sampling of primarily more male-typed domains, and (ii) an under-appreciation of gender differences in variance in priors. Our framework also helps provide additional insights into the mixed results on gender differences in asymmetry. Our results suggest that whether or not a good news – bad news asymmetry is observed is a function of how gender congruent the domain is, not simply a function of gender.

Across both educational and professional contexts, individuals regularly receive feedback on their own abilities. This information, even if unbiased, will almost always be noisy relative to the true object of interest. In this way, our experimental framework asks a question that is central to understanding the evolution of beliefs over time: how does new, noisy information shape beliefs of own ability? Our results suggest that policy interventions aimed at closing gender gaps in self-confidence that simply provide feedback to individuals may not have as strong of an impact as the Bayesian model would predict. Rather, gender stereotypes seem to impact the way new information is incorporated into beliefs, fueling persistence in gender gaps.

**Design of Study 1**

*Test of Cognitive Ability*

In our first study, participants take a test consisting of multiple-choice questions from the Armed Services Vocational Aptitude Battery (ASVAB). The ASVAB is an enlistment exam administered by the United States Armed Forces and taken annually by more than one million people (http://official-asvab.com/). In social science research, performance on the ASVAB has been used as a proxy for cognitive ability (see, for

---

[3] This is closest in design to the work of Eil and Rao (2011), who focus on relative ability but allow for belief distributions over all possible ranks in a population. Gender is not a focus of their study.

instance, Lusardi, Mitchell, and Curto 2010). We selected 30 total questions from five domains tested on the ASVAB: General Science, Arithmetic Reasoning, Math Knowledge, Mechanical Comprehension, and Assembling Objects. Participants have five minutes to answer as many questions as they can, and are told that they will receive $0.20 for each correct answer if this round of the experiment is selected for payment. Incorrect answers and skipped questions are not penalized.

*Elicitation of Priors*

Following their completion of the test, we elicit beliefs from participants. First, we ask each participant to guess their score -- their total number of correct answers -- on the test. We refer to this as a participant's prior belief of her absolute performance. Next, we ask each participant to provide a belief of relative ability. We ask them to consider how their performance on the test compared to the performance of all other participants completing the experiment. We asked them to choose which bucket they believed their relative performance would fall into: $0 - 5^{th}$ percentile, $5^{th} - 20^{th}$ percentile, $20^{th} - 40^{th}$ percentile, $40^{th} - 60^{th}$ percentile, $60^{th} - 80^{th}$ percentile, $80^{th} - 95^{th}$ percentile, $95^{th} - 100^{th}$ percentile. We explained these percentiles as identifying the percentage of other participants who performed better or worse than the participant. For each of these prior beliefs, we incentivize participants by offering them $0.10 if their guess is correct. In this way, we incentivize participants to provide the mode of their distribution over believed performance.

*Provision of Signals*

Participants are then randomly assigned to one of two signal treatments, either the *60% Signal Treatment* or the *90% Signal Treatment.* We vary *p* in order to study whether more informative feedback is more effective in correcting biased beliefs. Across both treatments, individuals receive a noisy signal of their performance on the test. With probability *p,* where *p* is either 0.6 or 0.9 depending on the treatment, the signal transmitted is exactly equal to their score on the test. With probability *1 – p,* the signal is equal to their score plus randomly-drawn "noise". The noise is drawn from a uniform distribution over non-zero integers between -5 and 5, that is: {-5, -4, -3, -2, -1, 1, 2, 3, 4, 5}.

We explain this mechanism to participants. They are told to imagine 10 balls, numbered $1 - 10$, in a bag. The computer will draw one of those balls at random. If the computer draws a ball with a number between $1 – 6$ (or 1 - 9 for those in the 90% Signal Treatment), the computer will show them their true test score. But, if the computer draws a number between $7 – 10$ (or just 10 in the 90% Signal Treatment), the computer will show them their true score plus some error "Ɛ", where "Ɛ" is equally likely to be any non-zero integer between -5 and 5. That is, the computer will take their score and add either -5, -4, -3, -2, -1, 1, 2, 3, 4, or 5 to construct their signal.

We tell them explicitly that they will just see their signal, not what ball the computer chose, or what "Ɛ" the computer chose. We then give them a few examples of how different scores, draws of balls from the bag, and values of "Ɛ" would produce different signals. We close by emphasizing that the computer will show them their true score 60%/90% of the time. They then answer a brief understanding question that they must answer correctly before continuing.

*Elicitation of Posterior Beliefs*

After they see their signal, participants are asked to provide another guess of their score on the test, incentivized in the same way as the prior. We will refer to this belief as a participant's posterior belief of her absolute performance on the test.

Finally, we collect some minimal demographic information about the participant: her gender, whether she attended high school in the United States, her race, and her educational attainment. Note that this beliefs experiment was embedded within a larger experiment aimed at exploring individuals' decisions about when to apply for promotion opportunities. All interventions related to this larger study occur after the beliefs experiment (but before the demographic information is elicited). That experiment is described in detail in Coffman, Collis, and Kulkarni (2019). Full experimental instructions are available in Appendix A.

*Implementation*

The experiment was run on Amazon Mechanical Turk in May 2018 with a total of 1,502 workers, of which 981 are assigned to one of the two signal treatments (the remaining participants receive no signal and so are excluded from this analysis as their posterior beliefs are not available). The study was advertised as a 30-minute academic research study that guaranteed a completion payment of $2.50 with the possibility of additional incentive pay. In Appendix Table B1, we present summary statistics on our workers by gender.

**Results of Study 1**

*Prior Beliefs*

There are significant gender differences in performance on the ASVAB test. We compute score as the total number of correct answers provided during the timed test. Men earn an average score of 11.3 (4.57 SD), while women earn an average score of 9.57 (4.20 SD). We reject the null of equality using a t-test with $p<0.001$.[4] On average, participants underestimate their absolute performance on the test when stating their

---

[4] According to the model of stereotyping in Bordalo et al (2016) and as applied in their work on beliefs about gender (Bordalo et al (2018)), this male advantage in performance at the mean may lead to beliefs about self that exaggerate

prior beliefs (after performance but before having received a signal). Men believe they answered 8.89 (4.16 SD) questions correctly on average, while women believe they answered 7.26 (3.86 SD) questions correctly on average (p<0.001). Recall that in this study participants are asked to guess what score they believe they earned. For simplicity, we will refer to this as their "prior", despite the fact that it is a point prediction rather than a distribution.

In Table I, we regress these prior beliefs of both absolute and relative ability on participant gender and performance. Conditional on performance, we estimate that women state beliefs of absolute score approximately 0.6 points lower than men (Column I, p<0.01). Similarly, women believe they place 7.5 percentage points worse in the ability distribution compared to equally able men (Column II, p<0.001). Interestingly, even when we control for a participant's pointwise prior belief of her absolute score, women believe they place worse in the distribution than men do (Column III). This suggests that the relative beliefs gap is driven not just by women believing they earned worse scores in absolute terms, but also by women believing others were more likely to earn better scores.

**Table I Here**

*Posterior Beliefs*

There remains a significant gender gap in beliefs conditional on score and signal received across both signal treatments. In Table II, we regress a participant's posterior belief of absolute score on their gender, their performance, and their signal received. Pooling over the two signal treatments, we see that women's beliefs remain about 0.5 points lower than men's conditional on receiving a noisy signal of performance (Column I). Conditional on having the same performance and after receiving identical signals, women's beliefs are 0.67 points lower than men's in the 60% signal treatment, and 0.42 points lower in the 90% signal treatment (Columns IV, VI, respectively). Note that in many ways, the 90% signal accuracy treatment represents a near "best-case scenario" for feedback: this feedback is highly accurate, immediate, and task-specific. And yet, it still fails to close the gender gap.

**Table II Here**

---

the male advantage on average. Because we study just one domain in Study 1, we cannot directly test for the role of stereotypes in shaping the gender differences we document. This question is instead a central focus of Study 2.

In a Bayesian setting, these differences in posterior beliefs (conditional on signal received) must be driven by differences in prior beliefs. A first step toward exploring the role of prior beliefs is to repeat this analysis while controlling for the priors that participants report. Pooling over the two signal treatments, we estimate that about half of the posterior gender gap is explained by priors (Column II). As one might expect, priors play a larger role in the 60% treatment where signals are noisier, explaining roughly 2/3 of the gender gap in posterior beliefs (see Column V). In fact, conditional on measured priors, there is no statistically significant gender gap in posterior beliefs in the 60% treatment. In the 90% signal treatment, priors play a less important role, explaining only 21% of the poster gender gap (Column VII). In the 90% signal treatment, women are significantly less confident than men after receiving a very informative signal of their performance, even conditional on stating the same prior.

Of course, given the design of Study 1, we cannot rule out that differences that remain after controlling for prior beliefs of most likely score could be driven by gender differences in prior distributions over all possible scores. That is, despite providing the same guess of their score, a man and a woman could have different distributions –for instance, in terms of variance or skewness - with that same mode. We return to this issue in Study 2, where we have full data on prior distributions.

Finally, we can ask whether there are gender differences in the extent to which different factors – prior beliefs, true ability, and signal received – are predictive of posterior beliefs. We perform this analysis in Column III, including interactions of female with prior, true ability, and signal received. We estimate that the gender difference in posteriors is driven in part by the fact that women's posteriors are significantly less responsive to signal received and significantly stickier to prior beliefs than men's posteriors are.

### *Whose Posterior Beliefs are More Accurate?*

We can also consider whether participants are updating in the direction of the truth – that is, are their posterior beliefs more accurate on average than their prior beliefs? The clear answer is yes. If we compute the mean error in beliefs, taking the absolute value of the difference between pointwise belief and true score for each individual, we see that the signals significantly reduce average errors, from 3.27 points in priors to 1.64 points in posteriors (p<0.001). The reduction is larger in the 90% signal treatment, where mean errors fall from 3.41 points to 1.32 points, than in the 60% signal treatment, (3.13 points to 1.97 points, difference-in-difference significant with p<0.001).

Across both signal treatments, men's posterior beliefs are on average significantly closer to the truth than women's are. Conditional on true score, signal received, and prior belief, women's mean errors in posteriors are 0.35 points larger than men's (p<0.01). Relative to the accurate beliefs benchmark, men's and women's

posteriors are still too underconfident on average, with participants updating in the correct direction but not enough.

Overall, we estimate that the gender gap in beliefs falls from 0.58 points to 0.53 points after the provision of signals; we cannot reject that these two gender gaps are the same. Thus, the provision of noisy but informative signals does not significantly reduce the gender gap in beliefs of own ability. In thinking about the magnitude of these gaps, it may be useful to normalize them against observed performance. The overall gender gap in priors is approximately 0.13 standard deviations of observed ability; this gap stays relatively flat, at approximately 0.12 standard deviations of ability, in posteriors. Of course, the fact that signals are dramatically reducing the mean error in beliefs implies that the gender gap relative to mean error in beliefs is increasing rather substantially. While the gender gap represents just 18% of the mean error in beliefs in priors, it represents 32% of the mean error in beliefs in posteriors.

Study 1 suggests that signals, while highly effective at reducing mean errors in beliefs, are not particularly effective at closing the gender gap in beliefs of own ability. The results raise a number of important open questions. Why do men and women with the same ability, the same prior belief of performance, and the same noisy signal of ability hold different posterior beliefs about their ability? Is it that men and women have different prior *distributions* over possible scores (a potentially Bayesian explanation for the results), or do men and women update differently in response to the news they receive conditional on prior beliefs (a non-Bayesian channel)? And, most centrally, to the extent that we see gender differences in prior distributions and updating, what underlies these differences? In particular, what is the role of gender stereotypes in shaping not only prior beliefs of ability, but also in predicting belief updating? To provide answers to these questions, we conduct a second experiment aimed at disentangling the role of differences in prior beliefs from differences in updating, and identifying the role of stereotypes in driving the gender differences we observe.

**Design of Study 2**

Study 2 builds on the paradigm of Study 1, but (i) explores a variety of domains and (ii) collects additional data on prior and posterior beliefs. Building on the approach of Coffman (2014) and Bordalo et al (2018), we select eight different domains that vary in their associated gender stereotype: Cars, Sports, Videogames, Business, Verbal Skills, Art and Literature, Disney Movies, and Kardashians.[5] While some of these categories lack the external career or educational relevance of the cognitive skills test from Study 1, their

---

[5] We document the associated gender stereotypes in Figure I in the results section.

clear associated gender-types allow for a better identification of the role of stereotypes in driving beliefs. For each domain, we construct a 20-question multiple-choice test to use as the task. Each multiple-choice test is a timed, 3-minute test, where participants are awarded 1 point for each correct answer. Skipped or incorrect answers are not penalized.

Participants complete three rounds of problem-solving and belief elicitation in the experiment. Each round is structured quite similarly to Experiment 1. First, the participant has three minutes to work on a multiple-choice test from one randomly-chosen domain. We then ask about prior beliefs. Each belief question is incentivized. As in Experiment 1, we ask the participant what they think their most likely score on the test was. But then, we collect additional information geared at better understanding the full distribution of prior beliefs. After reporting what they believe to be their most likely score, on the next page participants are asked the likelihood that they earned this exact score (i.e. "I believe there is a __% chance I earned exactly a score of 6"). After eliciting the probability mass they assign to the mode of their prior, we then ask them for their full distribution over all possible scores, reminding them of the probability mass that they assigned to the mode of their prior. The full instructions for this experiment are available in Appendix A. Finally, we ask participants what their believed rank is, comparing themselves to 100 other randomly-chosen participants who completed the same multiple-choice test.[6]

Following the elicitation of priors, we then provide signals of performance, using the language of Study 1. This time, however, we set signal accuracy at either $q=0.5$ or $q=0.7$, allowing us to collect more data from participants who receive inaccurate signals of ability. This will be useful in identifying asymmetry in responses to good and bad news. We then re-ask all the beliefs questions, including their believed most likely score, the probability they associate with this particular score, their full beliefs distribution over all possible scores, and their believed rank compared to 100 other participants. Participants receive no additional feedback before completing the next round of the experiment. The next round of the experiment is identical, except they see a new, randomly-drawn domain.

Following three rounds of the experiment, participants complete a brief demographic questionnaire that asks their gender, race, educational attainment, and whether or not they attended high school in the United States. We also include five unincentivized ASVAB questions as a proxy for cognitive skills, performance on which we use as a control variable when predicting beliefs. Finally, the very last question of the experiment asks them about the believed gender stereotype they associate with each of the eight possible domains in the experiment. They are given a slider scale that ranges from – 1 (women know much more)

---

[6] Unlike Study 1, here we allow them to guess any particular rank between 1 – 100. We incentivize them to report the mode of their prior over all possible ranks.

to 1 (men know much more) and are asked to indicate, using the slider scale, which gender on average they believe knows more about each domain.

*Implementation*

We conducted Study 2 on Amazon Mechanical Turk with a target of 2,025 participants (25 of which participated one day ahead of the full HIT to ensure the functionality of the programming) in October 2018. We exclude four participants who failed a basic attention check (failing to identify a picture within a time limit), leaving us with 2,021 participants.

The HIT was advertised as a 30-minute academic study that guaranteed a completion payment of $2.00 plus the possibility of incentive pay. Participants were told that one domain would be chosen at random to determine their bonus payment. For this randomly-selected round, they received $0.25 per problem solved correctly on the multiple-choice test. In addition, for all beliefs questions asked within the round, one was chosen at random as the "decision-that-counts". If the decision that counted was their believed score or believed rank, they received $0.50 if they guessed correctly. If the decision that counted was instead about the probability mass they assigned to a particular score, we used an adaptation of a BDM to incentivize truthful reporting. All participants were told that we were incentivizing them to tell the truth. They also had the option of clicking on a link that said "Here is why you should tell the truth" that explained the procedure in detail. Essentially, participants were asked to choose between a lottery that paid out with the probability mass that they assigned to a specific score, or a lottery that paid out with probability *X*. Participants were asked to provide the *X* that would make them indifferent between the two lotteries. The full language used to explain the procedure is available in Appendix A.

Note that during the running of the experiment, we noticed that there was an error in the specific click-through instructions to participants describing how truth-telling was incentivized for probability distribution questions. This error was corrected in the middle of the experiment, and a comparison of participant answers before and after the error correction finds no evidence that that error did impacted the answers given to the questions. A full analysis of this issue is presented in Appendix C.

**Results for Study 2**

Appendix Table B2 presents summary statistics for our participants in Study 2. We control for all demographic characteristics in our regression going forward. We chose the categories for Study 2 to vary in their associated gender stereotype, as measured by actual and perceived gender gaps in ability. Panel B of Appendix Table B2 confirms that our categories vary significantly along these dimensions. Figure I

illustrates the key data. We arrange the categories by the average slider scale rating given for the category among all participants. This average slider scale rating is graphed as the black line against the secondary y-axis. Four categories are perceived as being female-typed: Kardashians, Disney, Art and Literature, and Verbal Skills, while four categories are perceived as being male-typed: Business, Videogames, Sports, and Cars.[7] The bar graphs illustrate the average male and female score in each domain. The average gender gaps in performance correspond quite closely to the slider scale perceptions. In fact, if we correlate the male advantage in observed performance (gender gap in average test scores) within a domain with the average slider scale rating of that domain provided by participants, the correlation is 0.88. Note that there is significant heterogeneity in domain difficulty even within gender-type (thus, not all "hard" categories for women are gender incongruent, allowing us to separate difficulty from gender-type as explanatory factors).

**Figure I Here**

*Prior Beliefs*

We start by exploring the prior beliefs of participants. Our goal is to understand what gender gaps look like, conditional on true performance, and what role stereotypes play in predicting these gender differences. A key question then is how to measure the impact of stereotypes. We follow the approach of Bordalo et al (2018). Under this model, a decision-maker's belief about herself is shaped in part by comparisons of the distribution of performance of her own gender in a category compared to the distribution of performance of the opposite gender. Beliefs about own performance are then exaggerated in the direction of true gender gaps. That is, holding own individual ability fixed, the model hypothesizes that women's (men's) beliefs about own performance will increase as the average female (male) advantage in a category increases. In this way, stereotypes produce gender gaps in beliefs that are larger than (but directionally in line with) true gender gaps in performance.

Practically, we can test for a role for this type of stereotypical thinking by exploring whether the gender gap in average performance within a category is predictive of an individual's belief about herself, holding fixed her own measured ability. The hypothesis is that as own gender advantage within a category increases, an individual will report more optimistic beliefs about her own performance, holding fixed her own performance.

In Table III, we explore gender differences and self-stereotyping in prior beliefs of absolute ability and relative ability. First, in Column 1, we predict a participant's guess of her most likely score in a category from her gender, her own gender's average advantage in the category (as reported in row 3 of Table III),

---

[7] We will use these classifications when we refer to female-typed or male-typed domains going forward.

her observed performance, our demographic controls (whether or not she attended high school in the U.S., fixed effects for educational attainment, fixed effects for race, and her score on the ASVAB questions as a proxy of cognitive ability), round fixed effects, and category fixed effects. We estimate that, holding own ability fixed, women report prior beliefs approximately 0.5 points lower than men's for a gender-neutral category (average gender gap in performance of 0). More centrally, we see a strong role for stereotypes in shaping beliefs about self, replicating Bordalo et al (2018). We estimate that a 1-point increase in own gender advantage, roughly the size of the gender gap in business, decreases women's beliefs about their own ability by 0.16 points, while increasing men's beliefs about their own ability by 0.16 points. Other similar approaches yield similar results. For instance, if instead of predicting the mode of the participant's prior (her belief of her most likely score), we predicted the mean of her prior belief by computing the weighted average of her distribution over all possible scores that she reported, the results are nearly identical.[8]

In Columns II and III we turn to beliefs of relative ability, predicting a participant's believed rank among 100 participants who completed the quiz in that category (1=best, 100=worst). We estimate that women believe they place nearly 5 ranks worse than men conditional on having the same score in a gender-neutral category. And, we see a significant role for own gender advantage. In Column III we add the participant's prior belief of her absolute score as a predictor. We replicate our finding from Study 1: a significant role for stereotypes remains after controlling for beliefs of own absolute ability, suggesting gender gaps in relative ability are also driven in part by biased beliefs of *others'* ability.

<div align="center">

**Table III Here**

</div>

In Figure II, we attempt to visualize these differences. We graph the linear fit of absolute overconfidence (believed score – observed score) against true score for both men and women. We split the sample by whether the observation is from a male-typed or female-typed domain. This presentation of the data has the advantage of allowing us to compare estimates of overconfidence for men and women with the same score by comparing the height of the fitted line at different points in the score distribution. Essentially, we are interested in the height of each fitted line (and

---

[8] See Appendix Table B3 for these results. There, we also present results when we take a different approach to measuring the role of stereotypes, implementing the approach of Coffman (2014) and asking whether the average perception of the category as measured by the slider scale has predictive power for beliefs conditional on own measured ability. Essentially, we replace own gender advantage with own gender average perception (re-coding the sliding scales for women so that positive numbers always indicate an average perception in favor of own gender). Again, we see very similar results, with a strong estimated impact of own gender average perception of 0.72 points (p<0.001). That is, we estimate that moving from a gender-neutral category to a category that is perceived as 0.20 points on the slider scale toward male-typed (roughly the average rating of business), decreases women's beliefs of their own ability by 0.14 points and increases men's beliefs of their own ability by 0.14 points.

the vertical distance between the lines), for a given score.[9] As in Study 1, we observe underconfidence on average in our sample, but with overconfidence for lower ability participants and growing underconfidence for higher ability participants. Perhaps the most striking result from Figure II is the high degree of similarity in observed overconfidence of *men in male-typed domains* and *women in female-typed domains*. If we compare men and women's beliefs in domains that are gender congruent, there are no gender differences on average. The lines essentially lie on top of each other. Rather, we see more underconfidence from women than men only in male-typed domains. When we focus on female-typed domains, women are actually less underconfident than men.

**Figure II Here**

*Exploring the Shape of Prior Distributions*

After eliciting a participant's belief of her most likely score in the category, we then elicit her beliefs over all possible scores, gathering a complete picture of her prior distribution. In this sub-section, we explore the properties and shapes of those priors. For simplicity we focus on two key distributional measures: variance and asymmetry (skewness).

Our first finding is that women have tighter, lower variance priors than men on average. In Figure B1 in the Appendix, we display a histogram of the ranges of priors in our sample, split by gender. We define the range as the maximum score allotted positive probability in the prior minus the minimum score allotted positive probability in the prior. Many participants provide quite tight ranges – the median range is 4 and the mean range is 5.1. On average, women report narrower ranges than men (4.8 versus 5.5, p<0.001 clustering at individual level). We see a very similar pattern if we consider the individual standard deviations of priors. The average standard deviation of a prior distribution in our sample is 1.39, with women reporting lower variance distributions than men on average (average SD of 1.32 versus average SD of 1.51, p<0.001). Column I of Table IV also indicates that gender stereotypes seem to play a small role in

---

[9] We are not particularly interested in the slopes of each line, as these simply tell us how the degree of overconfidence varies with score. We know that score is a key factor for the degree of overconfidence (see Moore and Healy 2008 for example). So, it is important to control for score, which we do throughout our analysis and our visual presentation of the data.

predicting the variance in priors, with participants reporting more variant priors for more gender-congruent categories. This operates orthogonally to the main effect of female.

Next, we turn our attention to asymmetry or skewness in the prior. We start by defining three buckets of asymmetry in priors. We will define a "symmetric" bucket of distributions in which the mean of the distribution is also the median, a left-skewed bucket in which the median exceeds the mean, and finally a right-skewed bucket in which the mean exceeds the median. Approximately 21% of distributions are symmetric under this definition, 39% are left-skewed, and 40% are right-skewed. On average, the mean of a participant's prior is approximately 0.05 points greater than the median of her prior. We see modest gender differences in asymmetry that do not appear to be a function of gender stereotypes. Women are approximately 3pp less likely to report a symmetric prior than a man (Column II, p<0.05), and approximately 2.5pp more likely to report a right-skewed prior (Column IV, p<0.10). For all measures of asymmetry, gender stereotypes are un-predictive.

Thus, while stereotypes are strongly predictive of the mode/mean of priors, they are not very predictive of their shape. We observe that women report tighter priors than men, with lower ranges and standard deviations on average. And, women are marginally more likely to report a right-skewed prior.

**Table IV Here**

*Posterior Beliefs*

Do signals reduce the gender gap in beliefs, and in particular the reliance on stereotypes in shaping beliefs about own ability? Table V replicates Table III, but instead predicting posterior beliefs. [10,11] Throughout the analysis below, we will use "posterior" to refer to the mode of the posterior belief distribution for simplicity. Directionally, the estimated gender gap for a gender-neutral category and the reliance on stereotypes shrink in posterior beliefs of absolute ability compared to prior beliefs. However, both remain sizable and significant. While a 1-point increase in own gender advantage increased beliefs of own ability by an estimated 0.16 points in priors, the same shift in own gender advantage increases beliefs of own ability in

---

[10] Note that the vast majority of our participants receive a plausible signal. For 79% of observations, the mode of the prior belief distribution could have generated the observed signal. For 91% of observations, the participant put positive prior probability to at least one score that could have generated the signal. Only 162 signals fall outside of the 0 – 20 range. For completeness, we include all observations in our analysis.

[11] In addition, we control for the signal received and signal treatment.

posteriors by 0.14 points (see Column I, p<0.001).[12] It is clear stereotypes continue to impact posterior beliefs. In Column II, we ask whether more informative signals are any more effective in reducing reliance on stereotypes: do we see less reliance on gender stereotypes in the 70% signal accuracy treatment than in the 50% signal accuracy treatment? The clear answer is no, as the estimated interaction is very close to 0. As in Study 1, more informative feedback is no more effective in reducing gender gaps. Given the similarity of the results across the two signal treatments, we will consider them jointly in our remaining analysis.

**Table V Here**

We can also ask about "spillovers" onto beliefs of relative ability. Recall that our information provision focuses on absolute ability, providing a signal of absolute score on the test. However, one might expect that moving beliefs about absolute ability in the direction of the truth would also help to close the gender gap and the extent of stereotyping in beliefs of relative ability. In Column III we see that the signals do not reduce the gender gap in beliefs of relative ability, or the reliance on stereotypes in our data, as the coefficients on both are nearly identical in prior and posterior beliefs. Column IV again asks about the role of beliefs of absolute score in explaining gender differences in beliefs of relative ability, and we continue to see that stereotypes are predictive even conditional on posterior believed score.

Figure III replicates Figure II, this time plotting the linear fit of overconfidence in posteriors (differencing the mode of the posterior and true score) against score. Again, the focus is on comparing the height of different fitted lines, holding fixed a given score. We can clearly see that while average overconfidence has shrunk, relative to overconfidence in priors, the gender gaps are quite similar in size when compared to prior beliefs.

**Figure III Here**

---

[12] Again, the results look quite similar if we instead predict the mean of the posterior belief given the reported distributions over possible scores, or if we use slider scale perceptions instead of average gender gaps in performance to account for stereotypes. See Appendix Table B4. We can also explore the shape of posteriors, paralleling our analysis of prior beliefs. We find that both the degree of variance and the degree of asymmetry in prior beliefs are strongly predictive of variance and asymmetry, respectively, in posteriors. Conditional on the shape of priors, we see no gender differences or differences by gender stereotypes in shape of posteriors. Results available upon request.

### *How Well Does the Bayesian Model Predict Posterior Beliefs?*

One important question is whether these remaining gender differences are explained by gender differences in prior beliefs. We saw in Study 1 that gender gaps in posteriors were only partially explained by differences in prior guesses of most likely score across men and women. Our data in Study 2 are much more extensive, allowing us to provide a fuller test of the role for priors. In particular, for each participant, we can use her reported prior and the signal she received to make a Bayesian prediction for what the reported mode of her posterior should be. This Bayesian prediction tells us, given the signal structure, the full distribution of prior beliefs reported by the participant, including the probability mass she assigns to each possible score, and the signal she receives, what score a Bayesian decision-maker would report as the mode of their posterior. We do this for each person-round observation in our dataset.

In Appendix D, we present a simple Bayesian model that generates these predictions. The key takeaway is that, in our framework, the Bayesian prediction for most participants is of one of two types: the mode of her posterior should be either the signal she observed, or the mode of her posterior should be the mode of the prior she reported. The intuition is as follows: signals are accurate enough in our setting that, if a participant assigned sufficient probability to the signal in her prior distribution, she should update to that signal after observing it. If she did not put sufficient weight on her signal ex ante, then she should continue to report the mode of her prior as the mode of her posterior. In Appendix D, we formalize this intuition, developing propositions that characterize the Bayesian prediction for each participant.

For a small fraction of our participants, the Bayesian prediction is unclear: these are the participants who put no positive probability on any score that could generate the signal in their prior belief distribution. These participants have essentially seen a probability zero event. This occurs for 8% of men's observations and 10% of women's observations. We make the assumption in the analysis below that the most reasonable Bayesian prediction for these participants is to report their signal – this is the belief that would be justified by any (non-zero) flat prior over the scores that could generate the signal.

Turning to the rest of participants, for 51% of observations from men and 45% of observations from women, the Bayesian prediction is that the participant should report her signal. For 51% of observations from men and 56% of observations from women, the Bayesian prediction is that the participant should report the mode of her prior as the mode of her posterior. Finally, for 10% of observations from men and 11% of observations from women, the Bayesian prediction is some other score (not the signal or the mode of the prior) – this occurs only in the cases where the mode of the prior could not have generated the signal observed *and* there is sufficiently little weight on the signal in the prior distribution (see Proposition 2 in

Appendix D).[13] Note that these proportions do not sum to 100% because for some participants, the signal is also the mode of their prior.

With these Bayesian predictions, we can create a counterfactual – what would the population of posterior beliefs look like if every participant updated in accordance with Bayes rule? In a Bayesian world, would signals be sufficient to close the gender gap and reduce reliance on stereotypes? In Table V, Column I below, we predict the Bayesian-predicted posterior for each observation from our standard explanatory variables – gender, own gender advantage, performance, demographics, and round and category fixed effects. We see that the Bayesian model predicts a modest gender gap in gender-neutral categories, and a significant effect of self-stereotyping. Relative to the impact of stereotyping seen in priors (an estimated coefficient of 0.16), Bayesian posteriors would have stereotyping of roughly 5/8 the magnitude (an estimated coefficient of 0.10). Given that the impact of stereotypes in our observed posteriors (Column I of Table V, reproduced here as Column II in Table VI for convenience) is larger than this Bayesian prediction (0.14, or 7/8 the magnitude of the effect in priors), we have reason to suspect that there are departures from the Bayesian model in our data. Put differently, the effect of stereotypes is approximately 40% larger in our observed data than what the Bayesian model would predict, as can be seen by comparing the coefficient on own gender advantage in the counterfactual Bayesian world (Column I) and the coefficient on own gender advantage in the observed data (Column II).

**Table VI Here**

We can explore departures from the Bayesian predictions by predicting an individual's reported posterior belief *from her Bayesian prediction*. Column III presents the results. While the Bayesian prediction does have significant predictive power for observed posteriors, we see systematic departures from Bayes that are well-predicted by gender stereotypes. That is, we estimate a significant role for stereotypes *on top of* the role that the Bayesian model predicts.

First, we estimate a significant gender gap in posterior beliefs for gender-neutral categories, conditional on the Bayesian prediction. We estimate that women report posteriors roughly 0.3 points worse than men for a gender-neutral category, conditional on having the same Bayesian-predicted posterior. And, we estimate a significant impact of stereotypes. For every 1 point increase in own gender advantage, we estimate that

---

[13] For these participants, the Bayesian prediction is that the participant report the mode of her prior restricted to the set of scores that could have generated the signal. For those participants who have multiple modes in this space (176 of the 579 observations in this category), we take the average of those modes as the Bayesian prediction.

beliefs of own performance, *conditional on the Bayesian prediction*, increase by 0.10 points. That is, even after fully accounting for how stereotypes would impact posteriors through the Bayesian impact of prior beliefs, we estimate that stereotypes have significant predictive power for posterior beliefs. Stereotypes seem to color the way participants update in response to noisy information.[14]

Figure IV helps us to better understand what predicts departures from Bayesian predictions in our setting. We graph the linear fit of the **observed** posterior belief on the y-axis against the **Bayesian-predicted** posterior on the x-axis, graphing the fitted lines for both men and women in male-typed and female-typed domains. The vertical height between two fitted lines tells us, for a given Bayesian-prediction, whether there is a gender gap in the difference between observed posteriors and Bayesian-predicted posteriors. For instance, we could ask whether men's beliefs are lower, relatively to the Bayesian-prediction, than women's in male-typed domains by comparing the vertical distance between the solid blue line and the dashed red line.

**Figure IV Here**

Here, the slopes of the fitted lines are also informative, as they speak to how closely observed posteriors track Bayesian-predicted posteriors. A slope of 1 would indicate perfectly responsive beliefs. Slopes less than 1 indicate less responsiveness to the Bayesian predictions. Therefore, we also provide the 45-degree line as a point of reference.

Overall, we replicate past findings of conservatism: in general, beliefs are less responsive to Bayesian-predictions, as illustrated by the fact that slopes are less than 1. For both men and women, posteriors are more responsive to the Bayesian prediction when the domain is gender congruent. As we've seen in past figures, men and women in gender congruent categories behave quite similarly, with nearly identical average posterior beliefs conditional on the Bayesian prediction. In gender incongruent categories, both men and women hold relatively lower beliefs than what Bayes would predict compared to gender congruent categories (vertical height between solid and dashed lines), and their beliefs are less responsive to the Bayesian predictions (smaller slopes of dashed compared to solid lines).

---

[14] In Appendix Table B5, we repeat this analysis but using the mean of the Bayesian-predicted posterior and the mean of the posterior belief distribution and find very similar results. In Appendix Table B6, we repeat this analysis but excluding any individual who observed a "zero probability event", having put no prior weight on any score that could have generated the signal. The Bayesian prediction is more predictive in this model, but there continues to be an estimated impact of own gender advantage (estimated at 0.06 (SE 0.017)).

We formalize this finding in Table VII, predicting posterior beliefs from the Bayesian predictions and splitting the sample by male-typed and female-typed categories. We estimate that women hold significantly lower beliefs than men conditional on the Bayesian prediction in male-typed categories (Column I); this is driven by the fact that women's beliefs are on average less responsive to the Bayesian prediction (Column II). This pattern is reversed in female-typed domains, where men's posterior beliefs are less responsive to the Bayesian prediction than women's (Columns III, IV). In Column V, we produce the interacted model. We see that for an estimated gender-neutral category, there are *no* gender differences in how predictive the Bayesian prediction is for posterior beliefs. But, own gender advantage plays an important role. The Bayesian prediction better predicts posterior beliefs in gender congruent categories.

### Table VII Here

From a theoretical perspective, the Bayesian prediction incorporates all information about the participant prior that should be relevant for the mode of the posterior reported. In practice, however, different priors (and in particular modes/means of priors), despite generating the same Bayesian prediction, might lead to different participant behavior in terms of posteriors. Consider an example. Consider two participants both with a true score of 9 in a category. Suppose Participant A reports a mode of her prior of "7", while Participant B reports a mode of her prior of "9". Both then receive a signal of "9". It may be the case that the Bayesian prediction for both participants is to report the signal as the mode of their posterior (assuming Participant A puts sufficient weight on the possibility of her score being 9 in her prior). However, despite the Bayesian model making the same prediction, we may expect different responses – one could reasonably predict that Participant B is much more likely to report 9 as the mode of her posterior than Participant A would be, as the signal is more in line with Participant B's prior belief.

Our previous analysis asked – given the same Bayesian prediction for behavior – do men and women vary in their posterior beliefs. We could ask a slightly different question, which is, conditional on what we observe about participant priors – in particular, the mode of the prior, the prior weight assigned to it, the prior weight assigned to the signal, the standard deviation of the prior, and the degree of positive skewedness – do men and women vary in their posterior beliefs? Do stereotypes have predictive power conditional on having **not just the same Bayesian prediction**, but also the same salient features of priors?

We report the results in Table VIII, replicating our main results from the previous two tables (Column III of Table VI, Column V of Table VII). We see that including the mode of the prior in addition to the Bayesian prediction adds a lot of explanatory power to the model. Similarly, participants who have more variant priors and are more positively-skewed on average report greater posteriors conditional on other observables. The hypothesis above, that some priors make it "easier" to follow the Bayesian prediction, seems to be supported by the data. Interestingly, the particular weight assigned to the mode of the prior or to the signal ex-ante does not add predictive power beyond what the Bayesian prediction incorporates. It's simply the mode of the prior, likely proxying for how far away the Bayesian prediction is from the prior belief, and the shape of the prior, likely reflecting how uncertain the participant was, that seem to matter.

Conditioning on this additional information eliminates the estimated gender gap in posterior beliefs for a gender-neutral category; however, a significant, albeit smaller, role for stereotypes persists. It continues to be the case that, conditional on both the Bayesian prediction and more detailed information about participant priors, that own gender advantage shapes posterior beliefs. Column I indicates that own gender advantage leads to greater posterior beliefs of own performance, holding fixed all other factors, while Column II shows that this effect primarily operates through the fact that participants are more responsive to the Bayesian prediction as own gender advantage in the category increases.

**Table VIII Here**

*Good News, Bad News*

One interesting question that our framework allows us to consider is asymmetry in updating in response to "good" or "bad" news. Past studies, including Eil and Rao (2011) and Mobius et al (2014), have found that participants respond more to good news than bad news (relative to what the Bayesian model would predict) in ego-relevant tasks. With our data, we can ask, in an absolute ability framework, whether a similar asymmetry is observed. Furthermore, we can explore whether the extent of asymmetry varies with gender or gender-type of the domain.

To explore this question, we first define what it means to receive good or bad news. In our primary analysis, we will refer to a signal as good news if it is equal to or above their true score, and we will refer to a signal as bad news if it is below their true score.[15] Because the signal displayed is exogenous conditional on performance, this definition of news avoids any selection on priors or performance. Under this definition, it is **not** more likely that an underconfident participant receives "good news" than an overconfident participants receives good news; nor is it more likely that a talented participant receives "good news" than a poor-performing participant receives good news. This allows us to cleanly attribute differential reactions to good and bad news. This an important point, and one that is made possible by the absolute ability paradigm. Of course, these definitions of good and bad news may be a step removed from the participant's actual perception of whether the news is good or bad, which seems more likely to be defined relative to the mode or mean of their prior. In this way, our analysis is like an "intent-to-treat". In Appendix Table B9, we perform the same analysis relative to priors and find, in general, quite similar results.

We follow the econometric approach of Eil and Rao (2011). Suppose we predict posterior beliefs from the Bayesian prediction of posteriors. A good news or bad news effect could take two different forms. First, we could simply include a dummy to indicate that the news received was good (signal greater than or equal to score). A positive coefficient on this dummy would indicate what Eil and Rao (2011) refer to as a "generalized optimism" – beliefs that are on average greater than what the Bayesian posterior would predict for this particular type of news relative to when the same Bayesian prediction is made for bad news. We can also test for differential responsiveness to the Bayesian prediction for good news, indicated by a different slope on the Bayesian prediction depending upon whether the news was good. A steeper slope – indicated by a positive interaction term on the good news dummy and the Bayesian prediction – suggests greater responsiveness to the Bayesian prediction.

To simplify interpretations, we run a very basic model: we predict a participant's reported posterior belief from the Bayesian prediction for her posterior, a dummy for whether she received good news (which is purely exogenous), and the interaction of the two. We leave out all other explanatory variables so that we can interpret and compare constants across models simply. We split the data according to gender-type of the domain and gender. The results are presented in Table IX, Panel A.

**Table IX Here**

---

[15] We choose to include truthful news as "good news" since it is more likely that a truthful draw is greater than a participant's prior (61% of cases) then below a participant's prior (26% of cases).

Let's start by considering male-typed domains. Men and women display similar responsiveness to bad news in male-typed domains (with an estimated coefficient on the Bayesian prediction of 0.75 for both men and women). However, men have a larger estimated intercept for bad news than women do (a constant of 2.21 as opposed to 1.43). This suggests that after receiving bad news, men report larger posterior beliefs than women conditional on having the same Bayesian prediction. Turning to good news in male-typed domains, men are estimated to be much more responsive than women to the Bayesian prediction (estimated coefficient of 0.80 for men and 0.59 for women, $p<0.01$ in interacted model, see Appendix Table B7). It seems to be the case that women discount increasingly good news more than men do when it comes in a male-typed domain.[16] So, in male-typed domains, we estimate that the gender gap in posteriors after bad news is sizable (0.78 points), and flat over the range of Bayesian predictions. The gender gap in posteriors after good news in male-typed domains grows with the Bayesian prediction, eventually exceeding the gender gap in posteriors after bad news.

These patterns look quite different when we turn to female-typed domains, suggesting that much of the gender difference in responsiveness to good and bad news is a function of gender stereotypes. When we consider participants who receive bad news in a female-typed domain, women are more responsive than men (coefficient of 0.92 versus 0.78, $p<0.01$). We also estimate a smaller constant for women than men after receiving bad news (0.90 versus 1.39). This suggests that among participants with a very low Bayesian prediction, men will display greater overconfidence relative to that prediction than women; but, as the Bayesian prediction increases, given women's greater responsiveness, women will ultimately end up with higher beliefs conditional on the Bayesian prediction. After receiving good news, women are also much more responsive than men, exactly reversing the pattern we saw for male-typed domains (estimated coefficients of 0.79 and 0.67 for women and men, respectively, $p<0.01$, see interacted model in Appendix Table B7). We also estimate a smaller constant for women than men after receiving good news, again suggesting that for participants for whom the Bayesian prediction is quite close to 0, men's posterior beliefs will exceed the Bayesian prediction by more than women's do; however, given the differences in responsiveness, this gender gap reverses as the prediction increases.

An interesting consequence of these patterns is that we observe substantial differences in the predictive power of the Bayesian model by gender stereotype. When individuals are operating in a gender congruent domain, the model r-squareds are rather high (0.63 for men in male-typed domains, 0.72 for women in

---

[16] The estimated constant for women receiving good news is larger than the estimated constant for men (2.07 compared to 1.54), suggesting that for those whose Bayesian prediction is quite close to 0 women will be directionally more overconfident than men after receiving good news. However, given the differences in responsiveness, this pattern reverses quite quickly as the Bayesian prediction increases. Men's beliefs are estimated to exceed women's once the Bayesian prediction exceeds approximately 2.5.

female-typed domains). But, when individuals are operating in gender incongruent domains, posteriors are much harder to predict (r-squared of 0.46 for women in female-typed domains, r-squared of 0.52 for men in female-typed domains). The Bayesian model has much more predictive power in gender congruent domains than gender incongruent domains.

Panel B organizes the results from Panel A by gender congruence to help pull together the findings. To summarize, gender stereotypes play an important role in predicting asymmetry. Men and women are similarly responsive to good news when it comes in gender congruent domains: a responsiveness of approximately 0.80 for both. But, both men and women are much less responsive to that same good news when it instead comes in a gender incongruent domain: men's responsiveness falls to 0.67 in female-typed domains, and women's falls to 0.59 in male-typed domains. It is as if individuals react more to "stereotype-confirming" information – good news in a gender congruent task – than "stereotype-disconfirming" information – good news in a gender incongruent task. Thus, stereotypes matter (more than gender) for understanding differences in *responsiveness to good news*.

We can also observe that women, in general, seem to be more responsive to bad news than good news. This is true independent of the domain-type. While men are less responsive to good news than bad in female-typed domains, the same is not true in male-typed domains. Thus, in understanding asymmetry in the reaction to good and bad news, gender, not just gender stereotypes play a role. Women seem to be more responsive to bad news than good in a way that men are not.

Finally, it is worth emphasizing that the most challenging task would seem to be convincing individuals of their talent in gender incongruent domains. Across the four cells, individuals are least responsive to good news in gender incongruent domains. Men are least responsive to good news in female-typed domains. Similarly, women are least responsive to good news in male-typed domains. Responsiveness is lowest when individuals receive better than expected information in a gender incongruent domain.

In Appendix Table B8, we replicate these results using only the sub-sample of participants who put some positive prior probability on at least one score that could have generated the observed signal (the excluded participants are those who essentially observed an event that they assigned zero probability to in their prior). This ensures that the Bayesian prediction is clear for every participant in the sub-sample; however, it comes at the important cost of excluding those participants who are in some sense most over and under-confident in their prior beliefs. Among this sub-sample, the Bayesian predictions are in general much more predictive of posterior beliefs. But, we continue to find that individuals (both men and women) are more responsive to good news when it comes in a gender congruent domain than when it comes in a gender incongruent

domain. However, we find weaker evidence that women are more responsive to bad news than good, suggesting this may be driven by people who receive "large" surprises.

In Appendix Table B9, we replicate these results while defining good and bad news relative to priors, rather than relative to true scores. While this introduces potentially important selection into the receipt of good and bad news, it likely corresponds more closely to participants' impressions of whether news is good or bad. We find in general quite similar results.

**Conclusion**

There is increasing evidence that stereotyped beliefs drive important economic decisions – such as willingness to answer when unsure (Baldiga 2014, Coffman and Klinowski 2018), willingness to contribute ideas (Coffman 2014, Chen and Houser 2017, Bordalo et al 2018), willingness to compete (Niederle and Vesterlund 2007), and willingness to lead (Born et al 2018). Given this growing consensus, an important question is how persistent are these biased beliefs, and how do they evolve over time. In this paper, we take an important step toward addressing this question, asking how individuals respond to feedback about their abilities across different domains.

We replicate previous findings in showing a significant role for self-stereotyping in predicting beliefs of own ability absent feedback. We then show that self-stereotyping is also highly predictive of beliefs after feedback. This operates through two main channels: a Bayesian channel through which stereotypical prior beliefs fuel stereotypical posterior beliefs, and a non-Bayesian channel through which stereotyping shapes updating behavior. In particular, we see that individuals deviate from the Bayesian model, and these deviations are explained in part by gender stereotypes. Holding fixed the Bayesian prediction for beliefs, individuals hold more optimistic beliefs about their performance as the domain becomes more gender congruent. Within both of our experimental settings, more informative feedback is no more effective (and is in fact directionally less effective in our cognitive skills setting) in closing the gender gap or reducing reliance on gender stereotypes.

Both men's and women's beliefs are better predicted by the Bayesian model in gender congruent categories. In gender incongruent categories, participants' posterior beliefs are stickier to prior beliefs, and less responsive to good news in particular.

Our results have potentially important implications for policy-makers, educators, and organizational leaders looking to address gender gaps in self-confidence, particularly in male-typed domains. While a natural policy suggestion for addressing under-confidence on the part of talented women in male-typed domains is

providing feedback about own ability, our results suggest that stereotypes may inhibit the effectiveness of this strategy. In our setting, convincing an individual of their talent in a gender incongruent domain is much more difficult than convincing an individual of their talent in a gender congruent domain. This speaks to the pervasiveness and power of self-stereotyping. Stereotypes do not just impact beliefs about ability when information is scarce; rather, it appears stereotypes color the way information is incorporated into beliefs, perpetuating initial biases.

**Appendix C**

While the experiment was running on Amazon Mechanical Turk, we noticed an error in the instructions for why participants had an incentive to tell the truth for the distribution elicitation questions. Note that corrected instructions are available in Appendix A. The error related to the description of "Payment Option 2: The Bet On Your Score". Essentially, instead of offering participants a payment if their score was equal to the score they guessed (the correct structure), the instructions incorrectly copied the "Payment Option 1: The Lottery" language, suggesting that a random integer would be compared to their percentage. See the text below, including the highlight in yellow for the error.

*Payment Option 2: The Bet on Your Score*

*In the question above, you will tell us that you think there is a _____ % chance of your true score being equal to a given value. Let's call this value your "Percentage". That is, if you tell us that you think there is a 60% chance your true score is equal to the value, then your percentage is 60.*

*Then, we will draw a second an integer at random between 1- 100. Again, each integer (1,2,3,4,…, 96, 97, 98, 99, 100) is equally likely to be chosen. We'll call this number that's chosen the "Draw".*

*If the "Draw" number is less than or equal to your "Percentage" number, the lottery will pay you $1. If not, that is, if the "Draw" number is more than the "Percentage" number, the lottery will pay you nothing.*

Under this procedure, there is no clear financial incentive for truth-telling. The first 1647 participants saw this error in the instructions, while the final 374 participants viewed corrected instructions. We can test to see whether this error appears to impact the answers participants gave. The cleanest test is comparing the answers across participants for whom the error was fixed or not fixed. We can do this in a few ways. In Column 1 of Table C1 below, we can compare first responses across participants – that is, look at answers for the first question in which they saw these instructions (eliciting the probability assigned to the particular mode of their prior in the first round). First responses may be most reasonable because participants had to choose to view these instructions, and it is likely rates of viewing these instructions decrease with each opportunity to view them. In Column 2, we compare all responses to questions about the probability mass assigned to the mode of their prior. In Column 3, we compare all responses to questions about the probability mass assigned to the mode of their posterior. In each specification, the dummy for the error in the instructions is insignificant and the point estimate is close to 0 (recall that the outcome variable ranges from 0 – 100).

**Table C1. Evaluating the Error in the Instructions**

|  | OLS Predicting Probability Assigned to Mode of Prior – First Observation | OLS Predicting Probability Assigned to Mode of Prior – All Observations | OLS Predicting Probability Assigned to Mode of Posterior |

Notes: * indicates significance at p<0.10, ** at p<0.05, *** at p<0.01, and **** at p<0.001.

**Appendix D. Theoretical Framework**

Denote the decision-maker's true score on the test by T, where T $\in$ {0,1,2, ... , 30}. The decision-maker holds a prior belief over the distribution of possible test scores, such that for each possible test score, t, the decision-maker believes she earned that test score with probability, r(T=t), where:

$$\sum_{t=0}^{t=30} r(T = t) = 1$$

The mode of that prior distribution is t' such that r(T = t') > r(T = t) for all t $\neq$ t'.[17] The decision-maker then receives a signal of her performance, X, where X $\in$ {T-5, T-4, T-3, T-2, T-1, T, T+1, T+2, T+3, T+4, T+5}. We have that X = T with probability q, where q varies with treatment assignment.[18] After viewing the signal, the decision-maker then forms a posterior belief over the distribution of possible test scores, such that for each possible test score, t, the decision-maker believes she earned that test score with probability, s(T=t), where:

$$\sum_{t=0}^{t=30} s(T = t) = 1$$

The mode of that posterior distribution is t* such that s(T = t*) > s(T = t) for all t $\neq$ t*.[19]

What can we say about the beliefs a Bayesian decision-maker would hold after observing a signal in our framework? Conditional on having a score of T, she observes signal X = T with probability q. And, for each other score, t $\in$ {T-5, T-4, T-3, T-2, T-1, T, T+1, T+2, T+3, T+4, T+5}, she observes signal X = t with probability (1-q)/10.[20] Suppose now that the decision-maker observes a signal X = Z. This signal can be generated by 11 possible true scores. A true score of T=Z generates this signal with probability q. Any other true score in {Z-5, Z-4, Z-3, Z-2, Z-1, Z+1, Z+2, Z+3, Z+4, Z+5} generates this signal with probability (1-q)/10. No other true score can generate the observed signal X = Z. This implies that signal X = Z has been

---

[17] The case where no such t' exists, due to the decision-maker assigning equal likelihood to the two (or more) most likely scores, occurs with probability 0.

[18] In Study 1, we explore q = 0.6 and q=0.9. In Study 2, we explore q = 0.5 and q = 0.7.

[19] Again, the case where no such t* exists, due to the decision-maker assigning equal likelihood to the two (or more) most likely scores, occurs with probability 0.

[20] For each of these other scores, the signal process generates an incorrect signal with probability (1-q), and each incorrect score in the feasible range occurs with equal probability.

generated by a score of T = Z with probability q and by T = Z+i with probability (1-q)/10 for each i ∈ {-5,-4,-3,-2,-1,1,2,3,4,5}.

Now consider the role of her prior. We can use Bayes rule to write down an expression for a decision-maker's posterior probability of holding any particular score, given her prior belief distribution and the signal she has received. Denote the probability of observing the signal X = Z conditional on T = t by:

$p(X = Z|T=t)$

First, let's consider her posterior belief, s(T = t) for the case where t = Z. That is, having seen a particular signal, what will be the decision-maker's posterior belief of her true score being equal to that signal?

$$s(T = t = Z)$$

$$= \frac{p(X = Z|T = t = Z) \times r(T = t = Z)}{( p(Z = t|T = t = Z) \times r(T = t = Z) ) + \sum_{i=-5}^{i=5} p(X = Z|T = Z + i) \times r(T = Z + i)}$$

We can use the probabilities computed above, in particular p(X=Z|T=t=Z) = q and p(X=Z|T=Z+i) = (1-q)/10 for each i ∈ {-5,-4,-3,-2,-1,1,2,3,4,5}, to produce:

$$s(T = t = Z) = \frac{q\,r(T = t = Z)}{q\,r(T = t = Z) + \sum_{i=-5}^{i=5} \frac{(1 - q)}{10} \times r(T = Z + i)}$$

Of course, the same formula can be used to produce her posterior belief of holding any particular score, t≠Z, after having seen signal X=Z. In cases where Z ≠ t, we have:

$$s(T = t \neq Z)$$

$$= \frac{p(X = Z|T = t \neq Z) \times r(T = t \neq Z)}{( p(Z = t|T = t = Z) \times r(T = t = Z) ) + \sum_{i=-5}^{i=5} p(X = Z|T = Z + i) \times r(T = Z + i)}$$

First note that for all t such that t does not fall within {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}, we have p(X = Z|T=t) = 0, and thus s(T = t) = 0. In words, a Bayesian cannot justify placing positive probability on a score that could not have generated the observed signal X = Z. For all t in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}, we can sub in using the probabilities above to get:

$$s(T = t = Z) = \frac{\frac{(1-q)}{10} r(T = t \neq Z)}{q\, r(T = Z) + \sum_{i=-5}^{i=5}\frac{(1-q)}{10} \times r(T = Z + i)}$$

With these formulas, we can determine what the mode of a Bayesian's posterior distribution should be, as a function of the signal observed and her prior beliefs. The first natural question to ask is, when will the mode of a Bayesian's posterior be the signal she observed? That is, given $X = Z$, when will $t^* = Z$? In order for this *not* to be the case, we would need:

$$\exists t \in \{Z - 5, Z - 4, Z - 3, Z - 2, Z - 1, Z, Z + 1, Z + 2, Z + 3, Z + 4, Z + 5\}$$

*such that*

$$s(T = Z) < s(T = t)$$

Plugging in,

$$\frac{q\, r(T = t = Z)}{q\, r(T = t = Z) + \sum_{i=-5}^{i=5}\frac{(1-q)}{10} \times r(T = Z + i)}$$

$$< \frac{\frac{(1-q)}{10} r(T = t \neq Z)}{q\, r(T = Z) + \sum_{i=-5}^{i=5}\frac{(1-q)}{10} \times r(T = Z + i)}$$

Simplifying,

$$q r(T = Z) < \frac{(1-q)}{10} r(T = t)$$

$$r(T = t) > \frac{10q\, r(T = Z)}{(1 - q)}$$

This tells us that, in order for the signal received, Z, to *not* be the mode of the posterior, it must be the case that the decision-maker placed sufficiently little probability on her true score being equal to Z in her prior, relative to the probability she placed on at least one other score (that is feasible given the signal received). We can use the probabilities, q={0.5, 0.6, 0.7, 0.9}, from our experiments to reach the following propositions.

*Proposition 1.* Suppose a decision-maker observes $X = Z$ in the 50% signal accuracy treatment. Then, unless exists t such that r(T=t) > 10r(T=Z) with p(X = Z|T=t) > 0, it must be the case that the mode of her posterior is the signal she observed; that is, $t^* = Z$. Suppose a decision-maker observes $X = Z$ in the 60% signal accuracy treatment. Then, unless exists t such that r(T=t) > 15r(T=Z) with p(X = Z|T=t) > 0, it must be the

case that the mode of her posterior is the signal she observed; that is, $t^* = Z$. Suppose a decision-maker observes $X = Z$ in the 70% signal accuracy treatment. Then, unless exists t such that $r(T=t) > (70/3)r(T=Z)$ with $p(X = Z|T=t) > 0$, it must be the case that the mode of her posterior is the signal she observed; that is, $t^* = Z$. Suppose a decision-maker observes $X = Z$ in the 90% signal accuracy treatment. Then, unless exists t such that $r(T=t) > 90r(T=Z)$ with $p(X = Z|T=t) > 0$, it must be the case that the mode of her posterior is the signal she observed; that is, $t^* = Z$. Given that prior probabilities must sum to 1, this also implies that if $r(T=Z) > 1/11$ in the 50% treatment, $r(T=Z) > 1/16$ in the 60% treatment, $r(T=Z) > 3/73$ in the 70% treatment, or $r(T=Z) > 1/91$ in the 90% treatment, then it must be that $t^* = Z$.

Because of the informativeness of our signals, the mode of a Bayesian's posterior will be her signal, except in cases where she put very little weight on the signal being her true score in her prior. In those cases, what will be the mode of her posterior? We show below that, if the mode of the posterior is not the signal received, Z, then it must be the case that the mode of the posterior, $t^*$, is the mode of the prior over {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}. There are two cases to consider. In the first case, t' in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}. That is, the mode of the decision-maker's prior could have feasibly generated the signal observed.

Then, in this case, for it to be true that the mode of the decision-maker's prior is *not* the mode of the decision-maker's posterior, we would have to that there existed some $t_j$, where $t_j \neq Z$ and $t_j \neq t'$, such that $s(T = t_j) > s(T = t')$. Because we know $t_j \neq Z$, this implies:

$$\frac{\frac{(1-q)}{10} r(T = t_j)}{q\, r(T = Z) + \sum_{i=-5}^{i=5} \frac{(1-q)}{10} \times r(T = Z + i)} > \frac{\frac{(1-q)}{10} r(T = t')}{q\, r(T = Z) + \sum_{i=-5}^{i=5} \frac{(1-q)}{10} \times r(T = Z + i)}$$

Or, more simply:

$$r(T = t_j) > r(T = t')$$

But, this is a contradiction, as t' is the mode of the prior. Thus, it must be that if $t^* \neq Z$ and t' in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}, it must be that $t^* = t'$.

This leaves one remaining case, the case in which exists t in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5} such that $r(T=t) > ((1-q)/10)r(T=Z)$, so that the mode of the posterior is not the signal received, *and*, the mode of the decision-maker's prior could not have generated her observed signal, t'< Z-5 or t'>

Z+5. In these cases, the decision-maker should report as the mode of her posterior the value $t_j$ such that:

$s(T = t_j) > s(T = t_k)$ for all $k \neq j$ and $t_j, t_k$ in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}.

Plugging in,

$$\frac{\frac{(1-q)}{10} r(T = t_j)}{q\, r(T = Z) + \sum_{i=-5}^{i=5} \frac{(1-q)}{10} \times r(T = Z + i)} > \frac{\frac{(1-q)}{10} r(T = t_k)}{q\, r(T = Z) + \sum_{i=-5}^{i=5} \frac{(1-q)}{10} \times r(T = Z + i)}$$

Or, more simply:

$$r(T = t_j) > r(T = t_k)$$

In this case, the decision-maker should report the t in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5} for which r(T=t) is largest. Or, put differently, the decision-maker should report as the mode of her posterior the mode of her prior restricted to the distribution over {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}. This leads to the following proposition that fully covers the two cases in which t* ≠ Z.

*Proposition 2.* Suppose t* ≠ Z. Then, the mode of the posterior is the mode of the prior distribution restricted to {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}. In the event that t' in {Z-5, Z-4, Z-3, Z-2, Z-1, Z, Z+1, Z+2, Z+3, Z+4, Z+5}, then t* = t'.
